Tree-Ring Analysis of Timbers from White Hart Yard, 10-16 Cloth Market, Newcastle Upon Tyne, Tyne and Wear

A J Arnold, R E Howard and C D Litton

Summary

Samples were taken from timbers in both the front (roof, ground-floor and first-floor ceiling beams) and rear ranges of this building. Analysis undertaken on 31 samples resulted in 27 of these grouping to form site sequence NWCDSQ01. This site sequence contains samples from all areas sampled, and spans the period AD 1391-1529.

Prior to tree-ring analysis being carried out, this building was thought to date to the first half of the sixteenth century. It was uncertain, however, whether the ranges were contemporary or of slightly different dates. Dendrochronological dating has shown that the timbers from the rear-range roof were felled in AD 1527, with those from the ground and first-floor ceiling beams and the roof of the front range being felled two years later in AD 1529.

Introduction

The White Hart Yard site (Fig 1; NZ 246641), comprises one and one-half medieval burgage plots in one of the best-preserved sections of the pre-nineteenth century town. Development has grown from the front range along both sides of the plot around a central lane, closed to the rear (east) by the incursion of nineteenth-century Grey Street. It is thought to have originally been constructed in the sixteenth century, but was refronted in the late eighteenth century.

Front Range

This range consists of three storeys and four bays, with the third bay being a vehicle entrance to White Hart Yard (Fig 2). At ground-floor level, the bay to the left of the yard entrance has several large, close-set ceiling beams. The whole of the first floor is one large four-bay room, divided by heavy ceiling beams, between which are close-set joists with trilobe mouldings and elegantly run-out stops. The roof of this range is a ridge-braced kingpost and tiebeam roof structure. The sequence of carpenters' marks beside the ridge brace mortices on the king posts suggests that the roof is *in situ*. This part of the building has been dated on stylistic grounds to the first half of the sixteenth century.

Rear Range

This is a two-storey, four-bay wing. It is described as having similar heavy first-floor ceiling beams to those of the front range (English Heritage 2001), but at the time of the inspection and sampling these were no longer visible. It has a ridge-braced kingpost and tiebeam roof, of slightly cruder construction, but otherwise identical to that of the front range. A similar, if not identical date in the first half of the sixteenth century is suspected.

The Laboratory would like to thank Martin Roberts of English Heritage for his advice during assessment and John Nolan of Northern Counties Archaeological Services who provided Figures 2–15.

Sampling and analysis by tree-ring dating was commissioned and funded by English Heritage to inform the forthcoming conversion and restoration works, and to contribute to the establishment of a regional roof typology. By dating these ranges it was hoped to accurately date the fireplace, door jamb, and floor-joist moulding, by association.

Sampling

Core samples were taken from 35 oak beams, and each sample was given the code NWC-D (for Newcastle, site 'D) and numbered 01–35. Eleven samples were taken from ground and first-floor ceiling beams of the front range (NWC-D01–11), 12 from the roof structure of the front range (NWC-D12–23), and 12 from the rear-range roof (NWC-D24–35). The position of all samples was noted at the time of sampling and has been marked on Figures 3–15. Further details relating to the samples can be found in Table 1. Ceiling beams and roof trusses have been numbered from north to south (front range) and from east to west (rear range).

Analysis and Results

Four samples (NWC-D01, NWC-D24, NWC-D26, and NWC-D29) had too few rings to be dated securely, and so were rejected prior to measurement. The remaining 31 samples were prepared by sanding and polishing, and their growth-ring widths were measured; these measurements are given at the end of the report. Usually the ring widths of each sample are measured twice, with these two sequences of measurements then matched together to form an average sequence. When more than one core is taken from a single timber, each sample is measured once only, with all sequences from this timber again matched together to form an average sequence. In the case of NWC-D30 two core samples were taken, one of which had 60 rings and one had 30 rings. When these two sets of sequences were matched together at the relevant offset they formed an average sequence of 63 rings. These samples were then compared with each other using the Litton/Zainodin grouping procedure (see appendix).

Twenty-seven samples matched each other with a minimum *t*-value of 4.5, and were combined at the relevant offset positions to form NWCDSQ01, a site sequence of 139 rings (Fig 16). This site sequence was then compared to a large number of relevant reference chronologies for oak, indicating a consistent match when the date of its first ring is AD 1391 and of its last measured ring is AD 1529. The evidence for this dating is given by the *t*-values in Table 2.

Attempts to date the remaining four samples by comparing them individually to the reference material were unsuccessful, and these samples remain undated.

Interpretation

Analysis of 31 samples taken from timbers in the front and rear ranges of White Hard Yard, Newcastle, has resulted in the construction and dating of a single site sequence. Site sequence NWCDSQ01, of 139 rings, contains 27 samples, and spans the period AD 1391–1529.

Nine samples are from ceiling beams of the ground and first floors in the front range. Of these, seven have complete sapwood and a last measured ring date of AD 1529, the felling date of the timbers represented. The other two dated samples taken from the ceiling beams have similar heartwood/sapwood boundary ring dates. The average of these is AD 1502 which, taking into account sample NWC-D03 having a last measured ring date of AD 1527 with incomplete sapwood, allows an estimated felling date to be calculated for the two timbers represented to within the range AD 1528–42, consistent with a felling date of AD 1529.

All 12 samples from the roof timbers of the front range were successfully dated. Of these, three have complete sapwood and a last measured ring date of AD 1529, the felling date of the timbers represented. Five other roof timbers have heartwood/sapwood boundary ring dates consistent with a single felling. The average of these five heartwood/sapwood boundary ring dates is AD 1505, which, allowing for sample NWC-D23 having a last measured ring date of AD 1528 with incomplete sapwood, calculates to an estimated felling date for the five timbers represented to within the range AD 1529–45. The remaining four roof samples do not have the heartwood/sapwood boundary ring and so an estimated felling date range cannot be calculated for them. However, by adding the minimum expected sapwood rings (15) to the last measured ring dates of AD 1461 (NWC-D14), AD 1467 (NWC-D18), AD 1497 (NWC-D21), and AD 1504 (NWC-D22), this would provide *terminus post quem* dates of AD 1476, AD 1482, AD 1512, and AD 1519, respectively.

Six of the samples taken from the timbers of the rear-range roof are included in site sequence NWCDSQ01. Of these, four have complete sapwood and a last measured ring date of AD 1527. The average heartwood/sapwood boundary ring date of the other two roof timbers is AD 1506 which, given that sample NWC-D35 has a last measured ring date of AD 1524 with incomplete sapwood, allows an estimated felling date range to be calculated for the two timbers represented of AD 1525–46, consistent with a felling date of AD 1527. In calculating felling date ranges, this Laboratory uses the estimate that 95% of mature oak trees from this area have between 15–40 sapwood rings.

Discussion

Prior to the tree-ring analysis, the front and rear ranges had been dated to the first half of the sixteenth century on the basis of roof type and similarity to other dendrochronologically-dated roofs in the area, such as Kepier Hospital, West Range, Durham (AD 1522; Howard *et al* 1996) and the Rigging Loft, Trinity House, Newcastle (AD 1524; Howard *et al* 2002). However, it was uncertain whether the two ranges were contemporary or, if not, what difference in date there was between them.

Tree-ring dating has shown that the roof of the rear range is constructed from timbers felled in AD 1527, two years earlier than the front range roof and ceiling beams, which are built of timbers felled in AD 1529.

With the success of the dendrochronological dating, we now have precise dates for the roof and floor structures of the front range and roof of the rear range. In addition, the dating of the ceiling beams provides dating evidence for the type of moulding seen on these beams, information which might prove useful in other buildings. The design of fireplace and door jamb type seen at this building can now also be precisely dated by association with the dated timbers. The dating evidence of type of roof construction found here will be added to that already known and assist in the refinement of the roof typology for this area.

All 27 dated samples had matched each other to form a single site sequence. This suggests that the dated timbers from which this building was constructed were all from the same woodland source.

Tree-Ring Dating

The Principles of Tree-Ring Dating
Tree-ring dating, or *dendrochronology* as it is known, is discussed in some detail in the Laboratory's Monograph, '*An East Midlands Master Tree-Ring Chronology and its uses for dating Vernacular Building*' (Laxton and Litton 1988) and, *Dendrochronology; Guidelines on Producing and Interpreting Dendrochronological Dates* (English Heritage 1988). Here we will give the bare outlines. Each year an oak tree grows an extra ring on the outside of its trunk and all its branches just inside its bark. The *width* of this annual ring depends largely on the weather during the growing season, about April to October, and possibly also on the weather during the previous year. Good growing seasons give rise to relatively wide rings, poor ones to very narrow rings and average ones to relatively average ring widths. Since the climate is so variable from year to year, almost random-like, the widths of these rings will also appear random-like in sequence, reflecting the seasons. This is illustrated in Figure 1 where, for example, the widest rings appear at irregular intervals. This is the key to dating by tree rings, or rather, by their widths. Records of the average ring widths for oaks, one for each year for the last 1000 years or more, are available for different areas. These are called master chronologies. Because of the random-like nature of these sequences of widths, there is usually only one position at which a sequence of ring widths from a sample of oak timber with at least 70 rings will match a master. This will date the timber and, in particular, the last ring.

If the bark is still on the sample, as in Figure 1, then the date of the last ring will be the date of felling of the oak from which it was cut. There is much evidence that in medieval times oaks cut down for building purposes were used almost immediately, usually within the year or so (Rackham 1976). Hence if bark is present on several main timbers in a building, none of which appear reused or are later insertions, and if they all have the same date for their last ring, then we can be quite confident that this is the date of construction or soon after. If there is no bark on the sample, then we have to make an estimate of the felling date; how this is done is explained below.

The Practice of Tree-Ring Dating at the University of Nottingham Tree-Ring dating Laboratory

1. ***Inspecting the Building and Sampling the Timbers.*** Together with a building historian the timbers in a building are inspected to try to ensure that those sampled are not reused or later insertions. Sampling is almost always done by coring into the timber, which has the great advantage that we can sample *in situ* timbers and those judged best to give the date of construction, or phase of construction if there is more than one in the building. The timbers to be sampled are also inspected to see how many rings they have. We normally look for timbers with at least 70 rings, and preferably more. With fewer rings than this, 50 for example, sequences of widths become difficult to match to a unique position within a master sequence of ring widths and so are difficult to date (Litton and Zainodin 1991). The cross-section of the rafter shown in Figure 2 has about 120 rings; about 20 of which are sapwood rings – the lighter rings on the outside. Similarly the core has just over 100 rings with a few sapwood rings.

   To ensure that we are getting the date of the building as a whole, or the whole of a phase of construction if there is more than one, about 8 to 10 samples per phase are usually taken. Sometimes we take many more, especially if the construction is complicated. One reason for taking so many samples is that, in general, some will fail to give a date. There may be many reasons why a particular sequence of ring widths from a sample of timber fails to give a date even though others from the same building do. For example, a particular tree may have grown in an odd ecological niche, so odd indeed that the widths of its rings were determined by factors other than the local climate! In such circumstances it will be impossible to date a timber from this tree using the master sequence whose widths, we can assume, were predominantly determined by the local climate at the time.

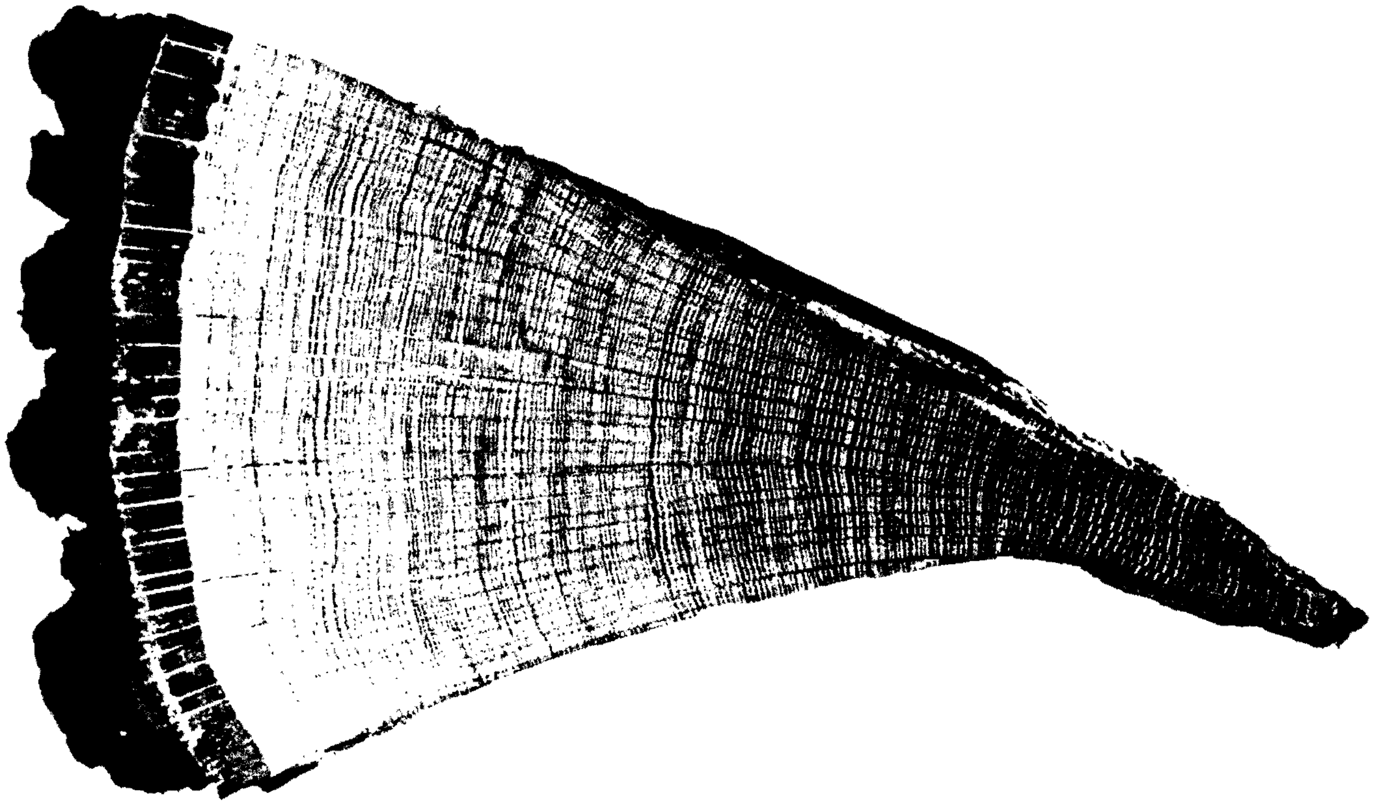

Fig 1. A wedge of oak from a tree felled in 1976. It shows the annual growth rings, one for each year from the innermost ring to the last ring on the outside just inside the bark. The year of each ring can determined by counting back from the outside ring, which grew in 1976.

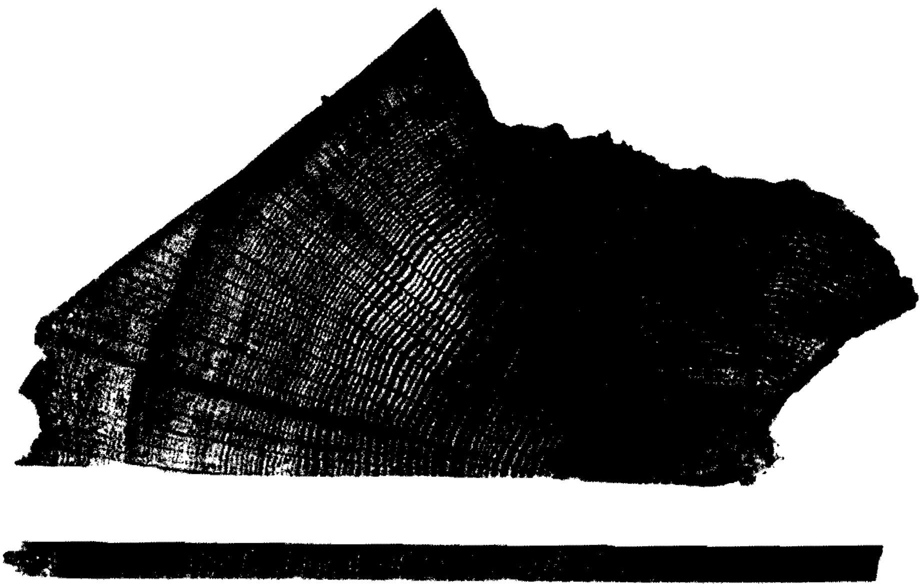

Fig 2. Cross-section of a rafter showing the presence of sapwood rings in the left hand corner, the arrow is pointing to the heartwood/sapwood boundary (H/S). Also a core with sapwood; again the arrow is pointing to the H/S. The core is about the size of a pencil.

Fig. 3 Measuring ring widths under a microscope. The microscope is fixed while the sample is on a moving platform. The total sequence of widths is measure twice to ensure that an error has not been made. This type of apparatus is needed to process a large number of samples on a regular basis.

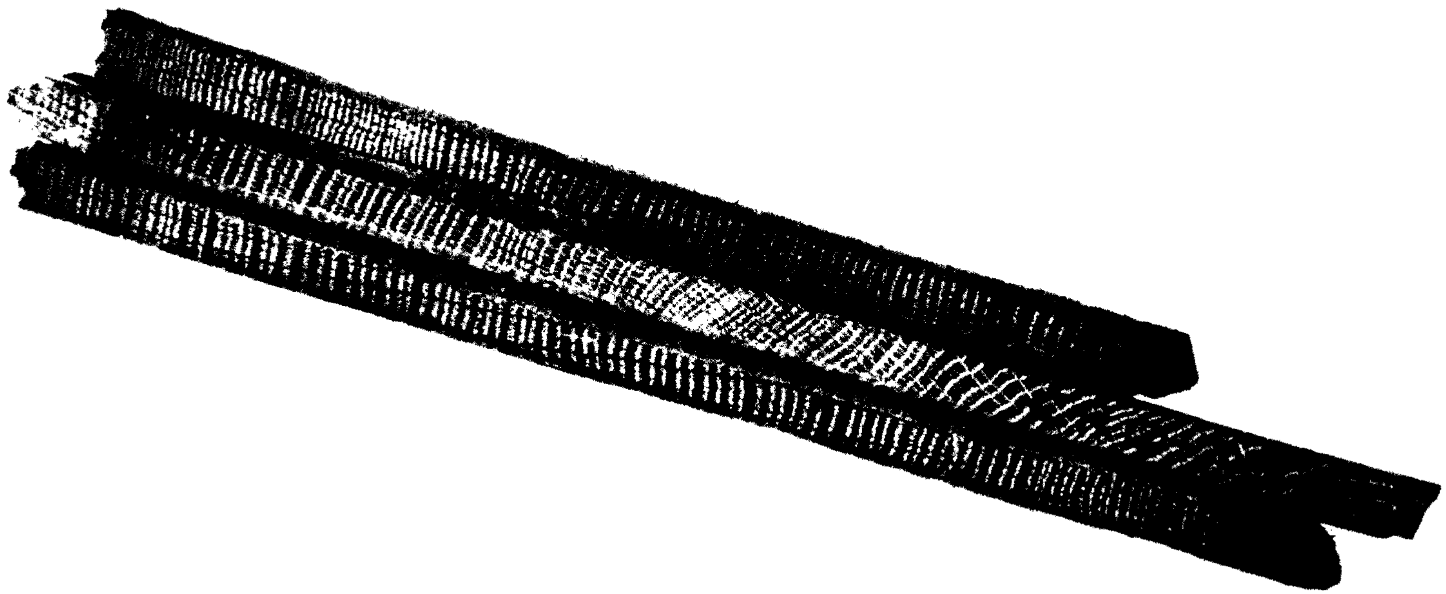

Fig 4. Three cores from timbers in a building. They come from trees growing at the same time. Notice that, although the sequences of widths look similar, they are not identical. This is typical.

Sampling is done by coring into the timber with a hollow corer attached to an electric drill and usually from its outer rings inwards towards where the centre of the tree, the pith, is judged to be. An illustration of a core is shown in Figure 2; it is about 15cm long and 1cm diameter. Great care has to be taken to ensure that as few as possible of the outer rings are lost in coring. This can be difficult as these outer rings are often very soft (see below on sapwood). Each sample is given a code which identifies uniquely which timber it comes from, which building it is from and where the building is located. For example, CRO-A06 is the sixth core taken from the first building (A) sampled by the Laboratory in Cropwell Bishop. Where it came from in that building will be shown in the sampling records and drawings. No structural damage is done to any timbers by coring, nor does it weaken them.

During the initial inspection of the building and its timbers the dendrochronologist may come to the conclusion that, as far as can be judged, none of the timbers have sufficient rings in them for dating purposes and may advise against sampling to save further unwarranted expense.

All sampling by the Laboratory is undertaken according to current Health and Safety Standards. The Laboratory's dendrochronologists are insured.

2. ***Measuring Ring Widths***. Each core is sanded down with a belt sander using medium-grit paper and then finished by hand with flourgrade-grit paper. The rings are then clearly visible and differentiated from each other with a result very much like that shown in Figure 2. The core is then mounted on a movable table below a microscope and the ring-widths measured individually from the innermost ring to the outermost. The widths are automatically recorded in a computer file as they are measured (see Fig 3).

3. ***Cross-matching and Dating the Samples***. Because of the factors besides the local climate which may determine the annual widths of a tree's rings, no two sequences of ring widths from different oaks growing at the same time are exactly alike (Fig 4). Indeed, the sequences may not be exactly alike even when the trees are growing near to each other. Consequently, in the Laboratory we do not attempt to match two sequences of ring widths by eye, or graphically, or by any other subjective method. Instead, it is done objectively (ie statistically) on a computer by a process called cross-matching. The output from the computer tells us the extent of correlation between two sample sequences of widths or, if we are dating, between a sample sequence of widths and the master, at each relative position of one to the other (offsets). The extent of the correlation at an offset is determined by the *t-value* (defined in almost any introductory book on statistics). That offset with the maximum *t*-value among the *t*-values at all the offsets will be the best candidate for dating one sequence relative to the other. If one of these is a master chronology, then this will date the other. Experiments carried out in the past with sequences from oaks of known date suggest that a *t*-value of at least 4.5, and preferably at least 5.0, is usually adequate for the dating to be accepted with reasonable confidence (Laxton and Litton 1988; Laxton *et al* 1988; Howard *et al* 1984-1995).

This is illustrated in Fig 5 with timbers from one of the roofs of Lincoln Cathedral. Here four sequences of ring widths, LIN-C04, 05, 08, and 45, have been cross-matched with each other. The ring widths themselves have been omitted in the *bar-diagram*, as is usual, but the offsets at which they best cross-match each other are shown; eg the sequence of ring widths of C08 matches the sequence of ring widths of C45 best when it is at a position starting 20 rings after the first ring of C45, and similarly for the others. The actual *t*-values between the four at these offsets of best correlations are in the matrix. Thus at the offset of +20 rings, the *t*-value between C45 and C08 is 5.6 and is the maximum found between these two among all the positions of one sequence relative to the other.

It is standard practice in our Laboratory first to cross-match as many as possible of the ring-width sequences of the samples in a building and then to form an average from them. This average is called a *site sequence* of the building being dated and is illustrated in Fig 5. The fifth bar at the bottom is a site sequence for a roof at Lincoln Cathedral and is constructed from the matching sequences of the four timbers. The site sequence width for each year is the average of the widths in each of the sample sequences which has a width for that year. Thus in Fig 5 if the widths shown are 0.8mm for C45, 0.2mm for C08, 0.7mm for C05, and 0.3mm for C04, then the corresponding width of the site sequence is the average of these, 0.55mm. The actual sequence of widths of this site sequence is stored on the computer. The reason for creating site sequences is that it is usually easier to date an average sequence of ring widths with a master sequence than it is to date the individual component sample sequences separately.

The straightforward method of cross-matching several sample sequences with each other one at a time is called the 'maximal *t*-value' method. The actual method of cross-matching a group of sequences of ring-widths used in the Laboratory involves grouping and averaging the ring-width sequences and is called the 'Litton-Zainodin Grouping Procedure'. It is a modification of the straight forward method and was successfully developed and tested in the Laboratory and has been published (Litton and Zainodin 1991; Laxton *et al* 1988).

4. ***Estimating the Felling Date***. As mentioned above, if the bark is present on a sample, then the date of its last ring is the date of the felling of its tree. Actually it could be the year after if it had been felled in the first three months before any new growth had started, but this is not too important a consideration in most cases. The actual bark may not be present on a timber in a building, though the dendrochronologist who is sampling can often see from its surface that only the bark is missing. In these cases the date of the last ring is still the date of felling.

Quite often some, though not all, of the original outer rings are missing on a timber. The outer rings on an oak, called *sapwood* rings, are usually lighter than the inner rings, the *heartwood*, and so are relatively easy to identify. For example, sapwood can be seen in the corner of the rafter and at the outer end of the core in Figure 2, both indicated by arrows. More importantly for dendrochronology, the sapwood is relatively soft and so liable to insect attack and wear and tear. The builder, therefore, may remove some of the sapwood for precisely these reasons. Nevertheless, if at least some of the sapwood rings are left on a sample, we will know that not too many rings have been lost since felling so that the date of the last ring on the sample is only a few years before the date of the original last ring on the tree, and so to the date of felling.

Various estimates have been made and used for the average number of sapwood rings in mature oak trees (English Heritage 1998). A fairly conservative range is between 15 and 50 and that this holds for 95% of mature oaks. This means, of course, that in a small number of cases there could be fewer than 15 and more than 50 sapwood rings. For example, the core CRO-A06 has only 9 sapwood rings and some have obviously been lost over time – either they were removed originally by the carpenter and/or they rotted away in the building and/or they were lost in the coring. It is not known exactly how many sapwood rings are missing, but using the above range the Laboratory would estimate between a minimum of 6 (=15-9) and a maximum of 41 (=50-9). If the last ring of CRO-A06 has been dated to 1500, say, then the estimated felling-date range for the tree from which it came originally would be between 1506 and 1541. The Laboratory uses this estimate for sapwood in areas of England where it has no prior information. It also uses it when dealing with samples with very many rings, about 120 to the last heartwood ring. But in other areas of England where the Laboratory has accumulated a number of samples with complete sapwood, that is, no sapwood lost since felling, other estimates in place of the conservative range of 15 to 50 are used. In the East Midlands (Laxton *et al* 2001) and the east to the south down to Kent (Pearson 1995) where it has sampled extensively in the past, the Laboratory uses the shorter estimate of 15 to 35 sapwood rings in 95% of mature oaks growing in these parts. Since the sample CRO-A06 comes from a house in Cropwell Bishop in the East Midlands, a better estimate of sapwood rings lost since felling is between a minimum of 6 (=15-9) and 26 (=35-9) and the felling would be estimated to have taken place between 1506 and 1526, a shorter period than before. (Oak boards quite often come from the Baltic and in these cases the 95% confidence limits for sapwood are 9 to 36 (Howard *et al* 1992, 56)).

Even more precise estimates of the felling date and range can often be obtained using knowledge of a particular case and information gathered at the time of sampling. For example, at the time of sampling the dendrochronologist may have noted that the timber from which the core of Figure 2 was taken still had complete sapwood but that none of the soft sapwood rings were lost in coring. By measuring into the timber the depth of sapwood lost, say 2 cm, a reasonable estimate can be made of the number of sapwood rings lost, say 12 to 15 rings in this case. By adding on 12 to 15 years to the date of the last ring on the sample a good tight estimate for the range of the felling date can be obtained, which is often better than the 15 to 35 years later we would have estimated without this observation. In the example, the felling is now estimated to *t*-value/offset Matrix

	C45	C08	C05	C04
C45		+20	+37	+47
C08	5.6		+17	+27
C05	5.2	10.4		+10
C04	5.9	3.7	5.1	

Bar Diagram

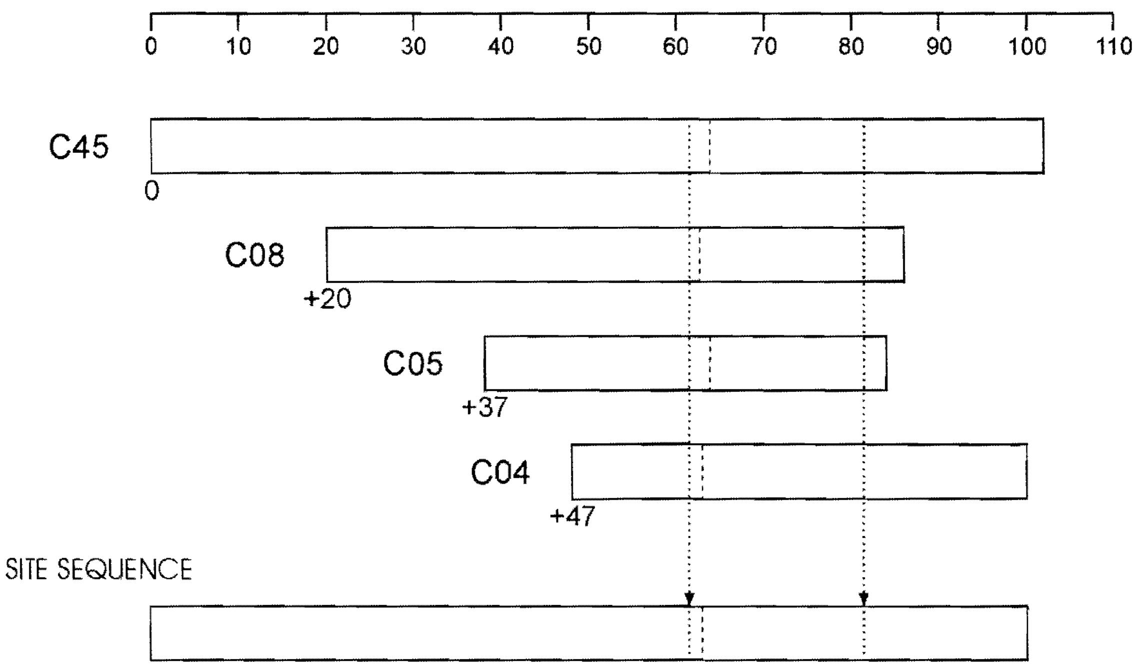

Fig 5. Cross-matching of four sequences from a Lincoln Cathedral roof and the formation of a site sequence from them.

The *bar diagram* represents these sequences without the rings themselves. The length of the bar is proportional to the number of rings in the sequence. Here the four sequences are set at relative positions (*offsets*) to each other at which they have maximum correlation as measured by the *t*-values.

The *t*-value/offset matrix contains the maximum *t*-values below the diagonal and the offsets above it. Thus, the maximum *t*-value between C08 and C45 occurs at the offset of +20 rings and the *t*-value is then 5.6.

The *site sequence* is composed of the average of the corresponding widths, as illustrated with one width.

have taken place between AD 1512 and 1515, which is much more precise than without this extra information.

Even if all the sapwood rings are missing on a sample, but none of the heartwood rings are, then an estimate of the felling-date range is possible by adding on the full compliment of, say, 15 to 35 years to the date of the last heartwood ring (called the heartwood/sapwood boundary or transition ring and denoted H/S). Fortunately it is often easy for a trained dendrochronologist to identify this boundary on a timber. If a timber does not have its heartwood/sapwood boundary, then only a *post quem* date for felling is possible.

5. ***Estimating the Date of Construction***. There is a considerable body of evidence collected by dendrochronologists over the years that oak timbers used in buildings were not seasoned in medieval or early modern times (English Heritage 1998 and Miles 1997, 50-55). Hence provided all the samples in a building have estimated felling-date ranges broadly in agreement with each other, so that they appear to have been felled as a group, then this should give an accurate estimate of the period when the structure was built, or soon after (Laxton *et al* 2001, figure 8 and pages 34-5 where 'associated groups of fellings' are discussed in detail). However, if there is any evidence of storing before use or if there is evidence the oak came from abroad (eg Baltic boards), then some allowance has to be made for this.

6. ***Master Chronological Sequences***. Ultimately, to date a sequence of ring widths, or a site sequence, we need a master sequence of dated ring widths with which to cross-match it, a Master Chronology. To construct such a sequence we have to start with a sequence of widths whose dates are known and this means beginning with a sequence from an oak tree whose date of felling is known. In Fig 6 such a sequence is SHE-T, which came from a tree in Sherwood Forest which was blown down in a recent gale. After this other sequences which cross-match with it are added and gradually the sequence is 'pushed back in time' as far as the age of samples will allow. This process is illustrated in Fig 6. We have a master chronological sequence of widths for Nottinghamshire and East Midlands oak for each year from AD 882 to 1981. It is described in great detail in Laxton and Litton (1988), but the components it contains are shown here in the form of a bar diagram. As can be seen, it is well replicated in that for each year in this period there are several sample sequences having widths for that year. The master is the average of these. This master can now be used to date oak from this area and from the surrounding areas where the climate is very similar to that in the East Midlands. The Laboratory has also constructed a master for Kent (Laxton and Litton 1989). The method the Laboratory uses to construct a master sequence, such as the East Midlands and Kent, is completely objective and uses the Litton-Zainodin grouping procedure (Laxton *et al* 1988). Other laboratories and individuals have constructed masters for other areas and have made them available. As well as these masters, local (dated) site chronologies can be used to date other buildings from nearby. The Laboratory has hundreds of these site sequences from many parts of England and Wales covering many short periods.

7. ***Ring-width Indices***. Tree-ring dating can be done by cross-matching the ring widths themselves, as described above. However, it is advantageous to modify the widths first. Because different trees grow at different rates and because a young oak grows in a different way from an older oak, irrespective of the climate, the widths are first standardized before any matching between them is attempted. These standard widths are known as ring-width indices and were first used in dendrochronology by Baillie and Pilcher (1973). The exact form they take is explained in this paper and in the appendix of Laxton and Litton (1988) and is illustrated in the graphs in Fig 7. Here ring-widths are plotted vertically, one for each year of growth. In the upper sequence of (a), the generally large early growth after 1810 is very apparent as is the smaller later growth from about 1900 onwards when the tree is maturing. A similar phenomena can be observed in the lower sequence of (a) starting in 1835. In both the widths are also changing rapidly from year to year. The peaks are the wide rings and the troughs are the narrow rings corresponding to good and poor growing seasons, respectively. The two corresponding sequence of Baillie-Pilcher indices are plotted in (b) where the differences in the immature and mature growths have been removed and only the rapidly changing peaks and troughs remain, that are associated with the common climatic signal. This makes cross-matching easier.

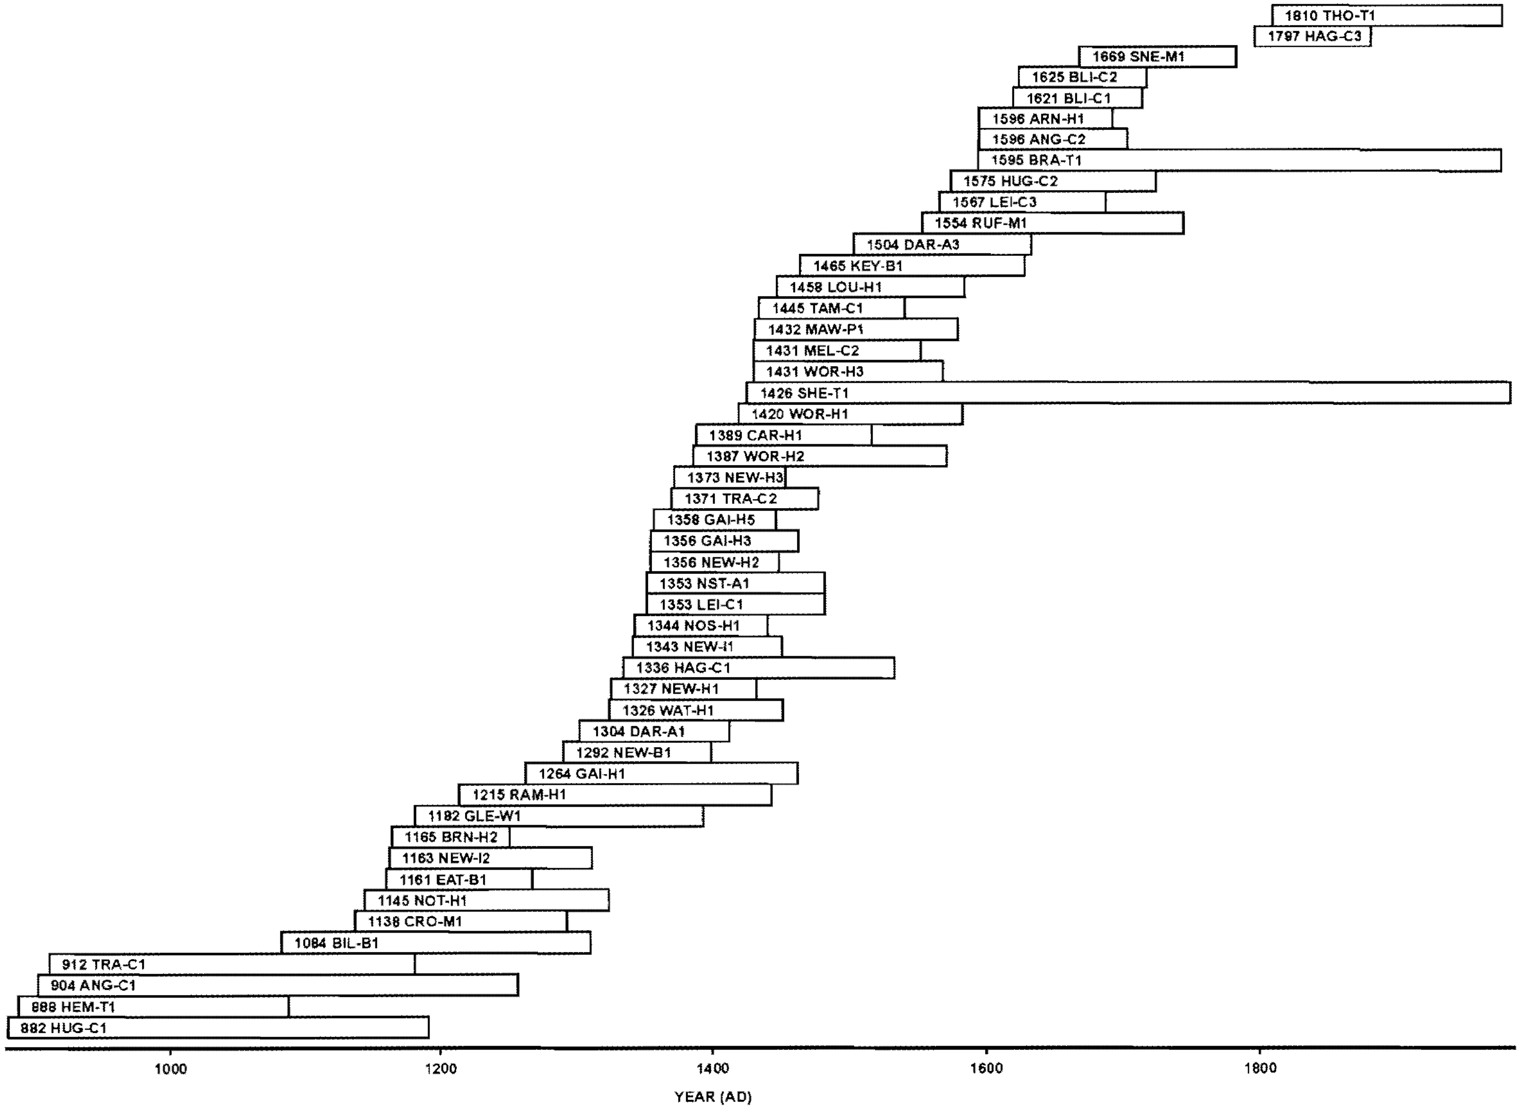

Fig. 6 Bar diagram showing the relative positions and dates of the first rings of the component site sequences in the East Midlands Master Dendrochronological Sequence, EM08/87

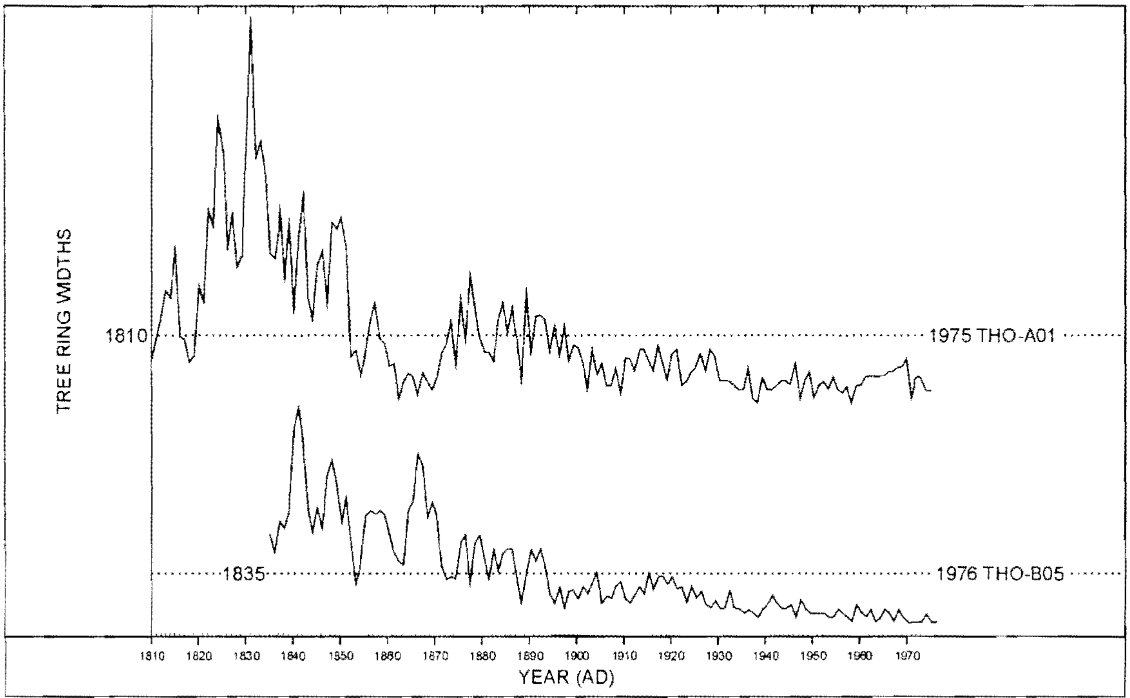
(a)



(b)

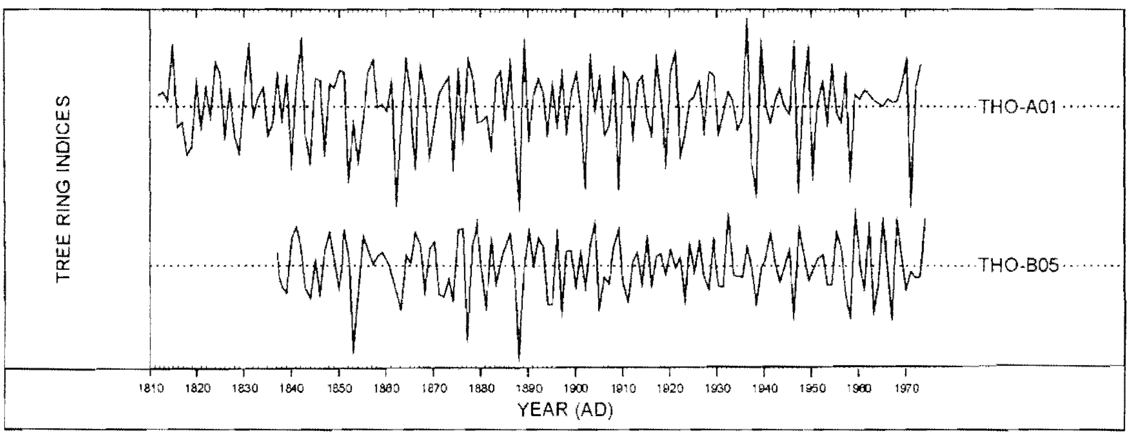


Fig 7. (a) The raw ring-widths of two samples, THO-A01 and THO-B05, whose felling dates are known. Here the ring widths are plotted vertically, one for each year, so that peaks represent wide rings and troughs narrow ones. Notice the growth-trends in each; on average the earlier rings of the young tree are wider than the later ones of the older tree in both sequences.

Fig 7. (b) The *Baillie-Pilcher* indices of the above widths. The growth-trends have been removed completely.
